Abstract. Coxiella burnetii is the causal agent of Q fever, a worldwide-distributed zoonosis, which is endemic in Spain. C. burnetii has an extensive reservoir, including farm animals and pets. The aim of this study was to determine the seroprevalence of C. burnetii in humans in Vallés Occidental (Barcelona, northeast of Spain) and its possible related risk factors. The prevalence of phase II antibodies from 216 subjects was determined by indirect immunofluorescence assay (IFA). Age, sex, living place, occupation, and contact with animals were surveyed. A 15.3% seroprevalence was found (≥ 1/40), and 8.8% of samples had titers ≥ 1/80. Seropositive cases were significantly higher in patients > 44 years of age. No statistically significant correlation was found between seropositivity and the remaining variables studied. Therefore, infection by C. burnetii seems to be endemic in our region, with a prevalence ranging from 9% to 15%, depending on the titers that are to be considered significant.

Coxiella burnetii is an obligate intracellular, small, gram-negative bacterium. This microorganism is the causal agent of Q fever, a worldwide-distributed zoonosis considered a public health problem in many countries. C. burnetii has an extensive reservoir, including many wild and domestic mammals, birds, and arthropods such as ticks. The most frequent sources of human infection are farm animals, especially cattle, goats, and sheep. It has been shown that infected cats, rabbits, and dogs can also transmit C. burnetii to humans. Animals are often chronically infected, shedding bacteria in feces, milk, urine, and especially, birth products of mammals.

The aerosol route is the primary mode of human infection. Contamination by aerosols may occur mainly from partrurient fluids. The organism may be spread by the wind; therefore, patients without any contact with animals could be infected. Ingestion (raw eggs and mainly, drinking raw milk) and person-to-person transmission (e.g., contact with parturient women, blood transfusion, autopsies, sexual transmission) are minor routes. C. burnetii is resistant in adverse conditions and can survive for months to years in a sporelike state, contaminating water or soil.

In humans, Q fever presents as a clinical polymorphism and usually is asymptomatic (~60% of the infections are asymptomatic seroconversions) or mild, as a flu-like disease with spontaneous recovery. The infection has two forms in humans: acute and chronic. In the acute form, clinical manifestations such as pneumonia, prolonged fever, and granulomatous hepatitis occur. The most frequent clinical manifestation of the chronic form is endocarditis. The acute form is often underdiagnosed because of a non-specific clinical picture, and thus serology is extremely important in the diagnosis of the disease.

Seroprevalence studies have a 2-fold interest: epidemiologic and diagnostic. The first shows the prevalence in a given geographical area. The second allows for adjusting the cut-off point of the serologic titers for diagnostic purposes in the study region.
housewives, 53 (32.9%) workers, and 26 (16.1%) unemployed. In seven people, the occupation was unknown.

Thirty-three (15.3%) of the sera samples analyzed showed antibodies against C. burnetii (≥ 1/40). Positive sera titers ranged from 1/40 to 1/1,280, and 19 (8.8%) had titers ≥ 1/80. Fourteen (6.48%) of the positive samples had an IgG titer of 1/40, 10 (4.63%) had a titer of 1/80, 3 (1.39%) had a titer of 1/160, 2 (0.93%) had a titer of 1/320, 2 (0.93%) had a titer of 1/640, and 2 (0.93%) had a titer of 1/1,280.

From 33 seropositive subjects, 19 (57.6%) were men and 14 (42.4%) were women (non-significant). C. burnetii seroprevalence was 16.10% in urban areas, 11.76% in semi-urban areas, and 18.75% in rural areas (Table 1), which was non-significant. There were no significant differences in the rates of antibodies to C. burnetii related to either contact with any kind of animals or occupation.

The prevalence of infection varied among the different age groups (Table 2). Seropositive cases were significantly higher in 45- to 64-year-old patients (P < 0.05; OR: 3.91). Of the 73 subjects > 44 years of age, 21 (28.8%) had titers ≥ 1/40, which was similar to those with ages between 30 and 44 years who had 9/43 seropositive titers (27.27%). In contrast, only 3 of 100 (3%) patients 0–29 years of age had positive titers against C. burnetii.

Coxiella burnetii infection is a public health problem in many countries, such as European countries, Canada, Japan, Turkey, Israel, and Australia.\textsuperscript{1,3,8–11} In Spain, Q fever is endemic,\textsuperscript{6,7,12} although its declaration is not mandatory. Therefore, epidemiologic and clinical features are known from research studies. Seropositive rates differ from one region to another, probably because of different epidemicologic and climatic environments. In effect, the highest seroprevalence data are found in northern Spain (Cantabria [48.6%],\textsuperscript{13} Basque country [38.5%]\textsuperscript{14}), Salamanca (50.2%),\textsuperscript{15} and Leon (40.6%),\textsuperscript{16} probably because of more cattle-raising activities. In contrast, Q fever seems to be less prevalent in central Spain (Madrid [12.7%]\textsuperscript{17}) and southern Spain (Huelva [4–6%]\textsuperscript{18}). In this study, the seroprevalence of C. burnetii was 15.3%, showing the endemic infection by C. burnetii in our predominantly urban area. This result agrees with those obtained in a previously carried study out in Catalonia (northeast Spain) whose seropositive rates ranged from 16% to 39%.\textsuperscript{19}

No statistically significant correlation was found between seropositivity and living place. Although seroprevalence has been considered higher in rural areas because farm animals are the main reservoirs,\textsuperscript{8,9,13,14,17,19} some studies have shown a rise in cases in people living in urban areas.\textsuperscript{20} Increased exposure to farm animals caused by travels to rural areas and outside activities, contact with pets, urbanization of rural areas, and windborne spread could contribute to the rising probability of being infected among urban residents.\textsuperscript{1,4,6,20,21} However, the small number of patients in our rural area requires conservative conclusions.

Q fever is more frequently in men in areas where the most common risk factor is exposure to infected cattle, including most European countries, California, and Australia.\textsuperscript{13,14,16,22} In contrast, our data showed a sex ratio similar to 1:1, proving that humans from our region could also be infected by other sources. For instance, exposure to parturient cats is the primary mode of C. burnetii infection in Nova Scotia, where the sex ratio are 1:1.\textsuperscript{23}

Although Q fever remains an occupational hazard among people in contact with farm animals,\textsuperscript{1,3,4,6,10,21} no significant difference was found between seropositive rates and either contact with animals or occupation. However, the small number of people who reported contact with animals may be a limitation.

Moreover, spread by the wind\textsuperscript{1,3,4} contact with pets,\textsuperscript{2,3,23} minor routes such as ingestion or person-to-person transmission,\textsuperscript{3,5} arthropod-borne transmission,\textsuperscript{24} and the resistance of C. burnetii in adverse conditions\textsuperscript{9} may contribute to humans being exposed to unknown sources. Therefore, further studies are necessary to elucidate risk factors in our region (predominantly urban).

Like other studies,\textsuperscript{13–16,23} seroprevalence to C. burnetii tends to increase with age. Significant prevalences of past infections in older ages could also be explained because of the longer exposure time experienced by older people.

Seroprevalence studies are essential to mark a cut-off point with diagnosis purposes. This is especially important in a dis-

\end{table}
ease like the Q fever, which has a rather unspecific clinical course, and where serologic results are determining. In our study, even considering a $\geq 1/80$ titer, 8.8% of the population was positive, which forces us to use titers $\geq 1/160$ for diagnosis purposes.

In conclusion, 15.3% of a sample of people representative of the Vallés Occidental County had antibodies against C. burnetii, which confirms the endemic nature of this infection.
