Abstract. The spread of Plasmodium falciparum drug resistance is outpacing new antimalarial development and compromising effective malaria treatment. Combination therapy is widely implemented to prolong the effectiveness of currently approved antimalarials. To maximize utility of available drugs, periodic monitoring of drug efficacy and gathering of accurate information regarding parasite-sensitivity changes are essential. We describe a high-throughput, non-radioactive, field-based assay to evaluate in vitro antimalarial drug sensitivity of P. falciparum isolates from 40 Senegalese patients. Compared with earlier years, we found a significant decrease in chloroquine in vitro and in genotypic resistances (>50% and >65%, respectively, in previous studies) with only 23% of isolates showing resistance. This is possibly caused by a withdrawal of chloroquine from Senegal in 2002. We also found a range of artemisinin responses. Prevalence of drug resistance is dynamic and varies by region. Therefore, the implementation of non-radioactive, robust, high-throughput antimalarial sensitivity assays is critical for defining region-specific prophylaxis and treatment guidelines.

Plasmodium falciparum, which causes the most virulent human malaria, is responsible for approximately one million deaths annually. Malaria related morbidity and mortality in sub-Saharan Africa presents a significant obstacle for economic development in this part of the world. Although a number of chemotherapeutic options are available for treating P. falciparum malaria, the rapid spread of drug resistance has marginalized the utility of many of these drugs. Chloroquine (CQ), quinine (QN), pyrimethamine, amodiaquine (AMQ), and artemisinin (ART) are among the most effective antimalarial agents. The latter two have been used in combination in many malaria endemic regions to thwart the emergence of drug resistance. In fact, the World Health Organization recommends the use of ART-based combination therapy (ACT) as a first-line regimen throughout much of Africa. However, monotherapy with ART and its derivatives has caused the emergence of parasites that show decreased sensitivity to these drugs, which is reflected in the higher IC50 values of some P. falciparum clinical isolates. Although clinical resistance to ART has not been adequately defined and reported, these decreased sensitivities may be the harbinger of clinical resistance. Periodic surveillance of drug efficacy through in vitro drug-sensitivity assays is essential for optimal selection of drug combinations, which will ensure successful administration of antimalarial treatment.

High-throughput methods that enable analyses of drug responsiveness of clinical isolates from different countries where malaria is endemic are essential to define antimalarial treatment regimens in those regions. For example, ACT is routinely and widely used for managing most malaria infections, sulfadoxine-pyrimethamine is still used for intermittent preventative treatment in pregnancy, and CQ remains an important option for parenteral use in severe disease. Moreover, drug-sensitivity testing would be needed for each geographically distinct region. Therefore, the implementation of non-radioactive, robust, high-throughput antimalarial sensitivity assays is critical for defining region-specific prophylaxis and treatment guidelines.
presenting with fever or those who had a history of fever and symptoms indicative of malaria were enrolled. The study protocol was approved by the Ethics Committee of the Ministry of Health in Senegal and the Human Subject Committee of the Harvard School of Public Health.

Before the start of the transmission season, microtiter plates were pre-loaded with antimalarial drug dilutions (serial dilutions of CQ [0.02–400 nM], AMQ [0.02–20 µM], ART [3.12–35 nM], and QN [23.47–75 µM] and stored at ~20°C until needed. Blood was collected from patients and transported on ice to the central laboratory. Only samples with 0.3% parasitemia or greater were used for the study. Inasmuch as this may introduce some bias, we were unable to use our method to obtain standard threshold 50% inhibitory concentration (IC$_{50}$) values for isolates with lower parasitemias. Packed erythrocytes were washed twice with RPMI (pH 7.4). The hematocrit of all samples was set to 2%, and samples with parasitemia greater than 1% were adjusted to 0.5–1.0% in complete medium using standard tissue-culture media. The cell suspension (180 µL per well) was dispensed into the thawed, pre-loaded, 96-well microtiter plates. The plates were incubated at 37°C in a gas environment of 5% CO$_2$, 1% O$_2$, and 94% N$_2$ for 72 hours. Smears prepared from zero drug wells were stained with Giemsa to ensure parasite growth at 72 hours. Samples that did not show any parasite growth in culture were eliminated from the subsequent analyses. At the end of the assay, the plates were frozen at ~20°C. The microtiter plates were then thawed at room temperature and centrifuged, and media were aspirated with care to avoid disturbing the red cell pellet. The fluorochrome mixture was prepared as previously described and dispensed in each well at a final dilution of 1:100,000 of DAPI (5 mg/mL stock; Molecular Probes, Inc., Eugene, OR). The microtiter plates were then incubated in the dark for 30 minutes and centrifuged at 4,000 rpm for 10 minutes. Excess fluorochrome mixture was aspirated, and 30 µL of 1× phosphate buffered saline (PBS) was dispensed into each well. The microtiter plates were read using a Fluoroskan plate reader (ThermoFisher Scientific, Milford, MA) with excitation and emission wavelengths of 355 nm and 460 nm, respectively. IC$_{50}$ values were calculated by non-linear regression analysis (GraphPad Prism, La Jolla, CA). Each antimalarial compound was evaluated in duplicate.

Parasite resistance to CQ, QN, and AMQ was defined based on standard threshold IC$_{50}$ values, above which parasites are classified as resistant (Table 1). The *P. falciparum* 3D7 laboratory strain was used to validate the DAPI assay under field laboratory conditions (Table 1). The IC$_{50}$ values for 3D7 parallel those obtained in other studies.

Fifty-one patient isolates with 0.3% parasitemia or greater were plated, and of these, 44 samples showed adequate growth at 72 hours. Of these, 40 samples had adequate data points to generate a non-linear regression curve and calculation of IC$_{50}$ for chloroquine. Fifty percent of these evaluable isolates were from female patients with an overall average age of 25 years and 2% parasitemia. Our analysis revealed that CQ resistance, defined as IC$_{50}$ values > 100 nM, was prevalent at the rate of 23% (9/40; Figure 1 and Table 1). The *P. falciparum* CQ-resistance transporter (PICRT) K76T polymorphism has been shown to be correlated with *in vitro* and *in vivo* CQ resistance and CQ treatment failure. We used standardized restriction fragment-length polymorphism to detect the PICRT K76T polymorphism in the 40 isolates. All of the nine isolates that were resistant to CQ (IC$_{50}$ > 100 nM) possessed the PICRT K76T polymorphism, and all of the 31 *in vitro* sensitive isolates were wild-type, resulting in an overall 23% genotypic resistance to CQ.

Interestingly, the *in vitro* and genotypic resistance rate was significantly reduced compared with resistance rates reported previously in this region. The *in vitro* CQ resistance in Pikine, a suburb of Dakar, was 53% in 2001 ($P = 0.0088$) and 52% in 2002 ($P = 0.0258$). Furthermore, the PICRT K76T polymorphism was 66% and 65%, respectively, in these previous studies. This reduction in two measures of CQ resistance rate parallels the withdrawal of CQ and introduction of other antimalarials in 2002 in Senegal. A similar reduction of CQ resistance after withdrawal of CQ had earlier been reported in Malawi. In that study, a rapid and progressive decrease in CQ resistance was observed after CQ withdrawal. In 1992, 85% of the isolates contained PICRT K76T. In 1993, the prevalence was 50% and had reduced to 13% by 2000. This observation prompted a CQ *in vivo* efficacy study in Malawi in 2005 and was found to be 99% effective. Thus, CQ, a cheap and well-tolerated antimalarial, could potentially be reintroduced as part of combination therapy in regions where CQ-sensitive strains of *P. falciparum* have reemerged. Indeed, Senegal may find itself in a similar position so long as the country refrains from using CQ mono-therapy for antimalarial therapy for the time being and undertakes constant surveillance of prevalence of drug resistance.

To protect the longevity and efficacy of ART and its derivatives, critical components of current antimalarial treatment options, it is essential for the partner drug in the combination therapy to be clinically effective. For example, in Cambodia, artesunate–mefloquine treatment failure was correlated with *in vitro* mefloquine resistance. In Senegal, artesunate–AMQ is a commonly used combination therapy. We, therefore,

Resistance against CQ, AMQ, and QN are defined as IC$_{50}$ values > 100 nM, > 60 nM, and > 800 nM, respectively. No clinical resistance threshold for ART has been established. Values in parenthesis indicate prevalence of resistance against each drug in the field isolates as a percentage.

![Figure 1](https://example.com/figure1.png)
determined the drug responsiveness of our isolates to AMQ and found the IC\textsubscript{50} values of all of them to be less than the resistance threshold of 60 nM.\textsuperscript{13}

We identified a larger range of IC\textsubscript{50} values among the isolates for ART with the highest value being >30 nM (Figure 1). Our data are consistent with those of Jambou and others,\textsuperscript{5} which also found a large range of IC\textsubscript{50} values (0.1–45 nM) for the ART-derivative artemether among clinical isolates in Senegal. No clinical resistance to date has been reported for the ART class of drugs in Africa. Thus, establishing baseline ART IC\textsubscript{50} values is critical to be able to monitor any future decrease in ART sensitivity because of widespread use of ACT in this region, and our data could potentially serve as baseline values for future artemisinin-sensitivity analysis.

QN continues to have important clinical indications for par- enteral treatment and severe disease. Our analysis revealed minimal resistance levels against QN. These levels have remained essentially unchanged (5% in Dakar in 2002).\textsuperscript{14} This absence of significant resistance may reflect the minimal selective pressure of QN (it is more commonly used than other drugs) and/or suggest that QN resistance does not arise as readily in the natural setting.

Drug-efficacy surveillance is critical for detecting the emergence of drug resistance and preventing its dissemination. Here, we describe an additional non-radioactive DAPI-based method to allow high-throughput screening for the prevalence of drug resistance in the field. We have used this method to determine the effect of withdrawal of CQ in 2002 on the prevalence of CQ resistance in Dakar, Senegal. Based on \textit{ex vivo} culture of parasites from patient isolates, our data indicate that the prevalence of CQ resistance has decreased from 53% in 2002 to 23% currently in Dakar. Our data also confirm the sensitivity of \textit{P. falciparum} in Dakar to AMQ, a commonly used partner drug in ACT in Senegal. However, we identified several isolates that exhibited elevated ART IC\textsubscript{50} values. Periodic screening should enable us to keep track of the spread of these isolates. Finally, \textit{in vitro} resistance does not necessarily correlate with clinical treatment failure, because antimalarial immunity (and perhaps other factors) impact \textit{in vivo} parasite clearance.\textsuperscript{22} Nonetheless, \textit{in vitro} drug-resistance patterns generally reflect parasite capacity to withstand chemotherapy in the field.\textsuperscript{23} Thus, extensive and periodic monitoring of drug efficacy and better control of unregulated drug usage is imperative.
