Abstract. A cross-sectional pilot study of hookworm infection was carried out among 292 subjects from 62 households in Kintampo North, Ghana. The overall prevalence of hookworm infection was 45%, peaking in those 11–20 years old (58.5%). In children, risk factors for hookworm infection included coinfection with malaria and increased serum immunoglobulin G reactivity to hookworm secretory antigens. Risk factors for infection in adults included poor nutritional status, not using a latrine, not wearing shoes, and occupation (farming). Although albendazole therapy was associated with an overall egg reduction rate of 82%, 37 subjects (39%) remained infected. Among those who failed therapy, treatment was not associated with a significant reduction in egg excretion, and nearly one-third had higher counts on repeat examination. These data confirm a high prevalence of low-intensity hookworm infection in central Ghana and its association with poor nutritional status. The high rate of albendazole failure raises concern about emerging resistance.

INTRODUCTION

It has been estimated that more than 600 million people worldwide, including 156 million children, are infected with hookworms, nematode parasites that attach to the intestinal mucosa and feed on blood.1,2 In sub-Saharan Africa, hookworm (Ancylostoma duodenale and Necator americanus) prevalence is approximately 30%,2 and in Northeastern Ghana, the prevalence has been reported to be as high as 50%.3 The effects of hookworm infection include growth delay, especially in children, and anemia, which, in pregnancy, is associated with poor birth outcomes.4 Infection is most prevalent in communities of rural poverty, because transmission occurs primarily through physical contact with soil contaminated by infective larvae.5,6 In these settings, coinfected with other endemic infectious diseases (e.g., malaria, human immunodeficiency virus [HIV], and tuberculosis) is also common, potentially compounding the negative sequelae of hookworm and other helminth infections.7,8

Hookworm control efforts have traditionally focused on community-based treatment of high-risk populations (for instance, school-age children) with benzimidazole anthelmintics. Periodic deworming has been shown to increase growth in some populations9 but not in others,10 whereas treatment of school children may decrease the risk of anemia.11,12 The 54th meeting of the World Health Assembly in 2001 called for ensuring access to anthelmintics “with the goal of attaining a minimum target of regular administration of chemotherapy to at least 75% and up to 100% of all school-age children at risk of morbidity by 2010.”13,14 However, repeated large-scale administration of benzimidazoles has raised concerns about the potential emergence of resistance, especially in light of evidence of reduced efficacy.15,16

We conducted a cross-sectional field study of hookworm infection in Kintampo North Municipality located in central Ghana. The primary purpose of this pilot study (292 subjects) was to define the epidemiology of hookworm infection, including associated risk factors and response to therapy, in an endemic population that had not previously been well-characterized. Evidence confirms a high prevalence of low-intensity hookworm infection in Kintampo North as well as significant rates of hookworm–malaria coinfection in children and young adults. We also report a high rate of treatment failure (39%) after administration of single-dose albendazole. Together, these data raise concerns about the potential for emerging benzimidazole resistance in Ghana, further highlighting the need for enhanced surveillance and monitoring of treatment efficacy in hookworm-endemic areas.

MATERIALS AND METHODS

Sample selection and surveys. This study was approved by the Yale Human Investigations Committee (protocol number 0705002669) and the Institutional Review Board of the Noguchi Memorial Institute for Medical Research (NMIMR) at the University of Ghana. In July 2007, four communities in Kintampo North Municipality of central Ghana were surveyed: Jato-Akuraa (JA), Cheranda (C), Kawampe (KA), and Gulumpe (GU). These communities were suspected to be endemic for hookworm infection based on anecdotal reports from providers at local health clinics. The two smallest and neighboring communities (JA and C) were analyzed as one community (JA/C). The three communities included approximately 1,200 households, 62 of which were sampled for this pilot study. The estimated sample size needed was determined based on the limited prevalence data for Kintampo North Municipality available from the Ghana Ministry of Health. Within each community, 20 households were selected at random based on government-assigned house numbers, with the intent to sample two adults and three children per house, yielding a total sample of approximately 300 participants. The final study population consisted of 292 participants from 62 households (Figure 1). More than one-half (51.2%) of the participants were 15 years old or younger; 258 individuals submitted a baseline stool sample and
a blood sample for analysis. Four participants were pregnant and excluded from analyses that relied on measurement of body mass index (BMI).

The study team visited each selected house to invite participation. After completion of the consent process, the team administered a short demographic and health questionnaire (see below), measured weight and height, and distributed labeled stool-collection containers. Stool samples were collected the following day, and approximately 2 mL blood were taken by venipuncture from each participant at that time.

**Survey instrument.** The study questionnaire was translated into Twi and back-translated into English by native speakers. Questions included information on age, gender, education, occupation, use of healthcare resources, previous use of anthelmintic drugs and other medications, perception of medical symptoms, shoe usage, latrine usage, daily activities, and other habits.

**Specimen collection and processing.** At the time of sampling, two drops of whole blood were used to create thick and thin smears on a microscope slide, and 20 μL were placed in 5 mL Drabkins solution for measurement of hemoglobin concentration. The remaining blood sample was separated by centrifugation, and the serum was stored at −80°C. Thick and thin blood smears were analyzed for the presence of *Plasmodium* species using light microscopy. Fecal samples were analyzed for the presence of helminth eggs on the day of collection using the Kato–Katz method. Individuals who were positive for hookworm or other soil transmitted nematodes (STNs) were treated with a single observed dose of 400 mg albendazole (Remedica, Limassol, Cyprus) within 1 week of detection. At 14–21 days post-treatment, a follow-up stool sample was obtained from those who had received albendazole to determine the efficacy of treatment.

**Measurement of serum immunoglobulin G against hookworm excretory–secretory proteins.** Total immunoglobulin G (IgG) antibody levels to *A. ceylanicum* excretory–secretory (ES) proteins were measured in serum samples from study subjects using a previously described enzyme-linked immunosorbent assay (ELISA). Serum samples (diluted 1:200) from study participants were incubated in ES-coated microtiter plate wells for 3 hours at room temperature. After washing, wells were incubated with horseradish peroxidase-conjugated goat anti-human IgG (diluted 1:5,000), and bound IgG was detected by adding ABTS (2,2'-azino-bis(3-ethylbenzthiazoline-6-sulphonic acid)) substrate solution (Sigma, St. Louis, MO). The absorbance was recorded using a SpectraMax 190 microplate reader (Molecular Devices Corporation), and the level of serum reactivity (optical density [OD] at 405nm) for the study population was categorized by quartile for statistical analysis.

**Comparison of in vitro anthelmintic activity of albendazole preparations.** The anthelmintic activity of the albendazole used in the study was evaluated using an in vitro egg hatch assay. Stock solutions of albendazole were prepared in methanol and diluted in distilled H2O to 6.0 μg/mL. Approximately 100 *A. ceylanicum* hookworm eggs extracted from the feces of infected laboratory hamsters were placed in individual wells of a 96-well microtiter plate along with increasing concentrations of albendazole. Plates were incubated at 27°C, and at 48 hours, the number of hatched first-stage (L1) hookworm larvae was counted under light microscopy. The hatch rate (percent) was determined by using the equation:

\[
\text{hatch rate} = \frac{\text{number of hatched larvae}}{\text{number of hatched larvae+number of remaining eggs}}
\]

Data were plotted to produce hatch rate curves comparing albendazole used in the field study (Remedica) with the identical drug purchased from Sigma.

**Statistical analysis.** All data generated from this study were stored in Microsoft Excel (2003), and statistical analysis was carried out in SPSS version 15.0. Statistical tests included parametric and non-parametric comparison of means, χ² tests, χ tests for comparison of proportions, and logistic regression analyses. Separate logistic regression analysis was conducted for adults (age > 15 years) and children (age ≤ 15 years) for baseline hookworm infection status. Initial variables tested were derived from a theoretical framework of factors thought to affect exposure and susceptibility to hookworm infection. Adjusted odds ratios are reported for significant variables, controlling for age, gender, and community.

**RESULTS**

**Study subject characteristics.** Individuals from 62 households participated in the survey, with an average of 4.2 subjects per household and a range of 1 to 9 subjects from each. The final sample included 20 households each from two communities (KA and GU) and 22 households from the third community (JA/C). Household size ranged from 1 to 88 people, with a median of 9 people. The ages of subjects ranged from 1 to 80 years, and 51.6% were female; 46% of the subjects were aged 10 years or younger, and 21% were aged 41 or older. Of the children aged 5–14, 74% were enrolled in school. Of those over age 15, 33% reported some primary or secondary school, and 64% were farmers.

Nineteen percent of the participants reported using a latrine, and 16% of the households reported having a pit latrine, all of which were shared. Overall, 13% of the study households used well water exclusively, whereas others also used pond water.

The overall rate of wasting (low weight for height) among children 5 years of age and younger was 6.5%, which is similar to a previously reported rate of wasting among children in Ghana (7.1%). More than one-half of those ages 15 and under had consulted a healthcare worker in the last year (60%) compared with 40% of the adults surveyed. Adults and children reported similar rates of fever in the past month.
(37% and 38%, respectively) and diarrhea in the last 6 months (24% and 31%, respectively).

Prevalence of geohelminths and malaria. The overall prevalence of hookworm in the study population was 45% (116 of 258 subjects), with 107 subjects (92.4%) classified as having light infection (<2,000 eggs per gram [epg] of feces). Only five (4.3%) subjects were moderately infected (2,000–3,999 epg), and four (3.4%) were heavily infected (>4,000 epg). Other intestinal parasites were present in fewer than 3% of the population, including *Hymenolepis nana* (3%), *Taenia solium* (1.1%), and *Trichuris trichiura* (1.2%). *Ascaris lumbricoides* was not detected. Figure 2A shows the age-related prevalence of hookworm infection, which was lowest in children under 6 years of age (20.5%) and highest in the 11–20 year age group (58.5%). The prevalence in children under age 6 was significantly different from the prevalence in the 6–10 and 11–20 year age groups (*P* < 0.05). The overall prevalence of a positive blood smear for malaria (*Plasmodium falciparum*) was 54% and was highest (81%) in children 6–10 years old (Figure 2A). Of note, all study participants with malaria were asymptomatic. The prevalence of malaria in children ages 6–10 was significantly different from all older age groups (*P* < 0.05). The prevalence of coinfection with both malaria and hookworm (Figure 2B) was highest in children ages 6–10 (51%) and lowest in adults ages 41–60 (10%).

Using univariate analysis, there was no statistically significant association of hookworm infection status with gender, community of residence, or history of anthelminthic treatment in the past year (Table 1). In children (ages ≤15 years), demographic factors associated with hookworm infection included level of education (*P* < 0.01), occupation (student versus nonstudent; *P* < 0.01), and malaria parasitemia (*P* = 0.015). There was no association between hookworm infection and shoe use or access to latrines. Among those 15 years and younger, the mean age of those infected with hookworm (8.37 ± 2.8 years) was significantly higher than those who were negative for hookworm (5.95 ± 3.37 years; *P* < 0.001).

In subjects older than 15 years, there was no association between hookworm infection status and level of education or malaria parasitemia (Table 1). However, in contrast with the younger cohort (≤15 years), hookworm infection status in this group was associated with occupation (*P* < 0.001), shoe use (*P* < 0.01), and access to a latrine (*P* < 0.001). In addition, the average BMI of those older than 15 years who were hookworm-positive (20.5) was significantly lower than in those who were hookworm-negative (22.1; *P* < 0.01). Although only 15.6% of adults with a BMI >23 were hookworm-positive, 54% of those with a BMI ≤23 were hookworm-positive at baseline, a difference that was statistically significant (*P* < 0.001). Figure 3 shows the distribution of BMI as a function of baseline hookworm infection.

Using multivariate analysis, hookworm infection in children was associated with a positive malaria smear when controlling for age, gender, and community (Table 2). The adjusted odds ratio (OR) for infection with hookworm in children with malaria was 2.84 (95% confidence interval [CI] = 1.11, 7.26) compared with those without malaria. Infection was also associated with serum reactivity to hookworm ES antigens (Table 2). Children in the second (OR = 5.43; CI = 1.59, 18.54), third (OR = 4.97; CI = 1.26, 19.68), or fourth (OR = 6.24; CI = 1.72, 22.65) highest quartile of serum reactivity to hookworm ES were significantly more likely to have hookworm infection than those in the lowest quartile (Table 2).

In those over 15 years of age, statistically significant risk factors for hookworm infection included farming as an occupation (OR = 4.89; CI = 1.90, 12.61), lack of latrine use (OR = 6.10; CI = 2.09, 17.54), and infrequent wearing of shoes (OR = 4.06; CI = 1.57, 10.53) (Table 2). Likewise, a higher BMI was associated with decreased prevalence of hookworm infection (OR = 0.71; CI = 0.60, 0.85) when adjusted for age, gender, and community (*P* < 0.01). In contrast to younger subjects, this group showed no statistically significant association between serum IgG levels against hookworm ES products and baseline infection status.

Prevalence of anemia. The overall prevalence of anemia in the study population was 51%, and it varied by age and hookworm/malaria infection status (Figure 4). In children ages 6–15 years, a positive blood smear for malaria in the absence of concurrent hookworm infection was significantly associated with anemia (OR = 4.92; CI = 1.05, 23.09; *P* = 0.04) compared with those without either infection (Table 3). By contrast, in this age group, there was an approximately twofold increase in the risk of anemia with hookworm...
(but not malaria) infection (OR = 1.99; CI = 0.27, 14.89), a difference that was not statistically significant ($P = 0.5$). Despite the increased risk in children singly infected, the risk of anemia in children positive for both hookworm and malaria was comparable with that in subjects with hookworm alone (adjusted OR = 2.34; CI = 0.56, 9.84), and the difference was not statistically significant ($P = 0.25$). These data suggest that concurrent low-intensity hookworm infection is associated with a reduced risk of malarial anemia, at least in school-age children. Of note, in older age groups (> 15 years), anemia was not significantly correlated with hookworm or malaria infection status, when controlling for age, gender, and education.

**Response to treatment with albendazole.** One hundred two individuals who were positive for hookworm infection at baseline were treated with a single 400-mg oral dose of albendazole; 95 individuals provided follow-up fecal samples. Based on follow-up fecal exams, the cure rate was estimated at 61.1%, with an overall egg reduction rate of 81.5% (Table 4). Of 37 individuals (39%) who failed albendazole therapy, 14 showed an increase in fecal egg excretion on follow-up exam. Within the group that failed therapy, the difference in fecal egg excretion pre- and post-treatment was not statistically significant (317 epg at baseline versus 187 epg at follow-up; $P = 0.084$). There was also no significant difference in baseline fecal egg excretion between those who were cured (215.9 epg) and those who failed treatment (314.7 epg; $P = 0.25$), evidence that intensity of infection was not a factor mediating response to albendazole.

To confirm that the albendazole used in the study was fully active against hookworm, an *in vitro* analysis of drug efficacy was carried out using a laboratory strain of *A. ceylanicum*.25– 27 As shown in Figure 5, there was no detectable difference in anthelminthic activity between the study drug (Remedica)
and newly purchased albendazole (Sigma). It is, therefore, unlikely that inadequate storage or poor-quality pharmaceutical manufacturing explain the high treatment failure rate in this population.

**DISCUSSION**

Hookworm infection is widespread throughout the tropics, with negative effects on the health and productivity of hundreds of millions of people. Across sub-Saharan Africa, the prevalence of hookworm is approximately 29%, corresponding to nearly 200 million people being infected. At present, there is no available vaccine to prevent hookworm infection, leaving periodic deworming and avoidance of risk behavior as the only effective measures of disease control.

Although prior studies of hookworm infection in Ghana have been published, most recent work has focused on populations in the northern part of the country. By contrast, little is known about the age-associated prevalence, intensity, social/demographic factors, and patterns of other infectious diseases in the Kintampo North Municipality located near the center of the country. To address this lack of baseline information, we conducted a cross-sectional pilot study to define the epidemiology of hookworm infection in this region of central Ghana. The data confirm a high prevalence (45%) of low-intensity hookworm infection that is comparable with published data from West Africa. In addition, we found a peak prevalence in school-age children, similar to previous findings from Africa but different from the steadily increasing prevalence with age reported from Asia.

The risk of contracting hookworm correlates with behavioral, social, and economic factors that mediate potential exposure, including lack of access to a latrine, crowded households, and overall socioeconomic status. Risk factors identified in this population confirm these findings but also link infection with general health status (BMI and concurrent malaria infection) and occupational exposure (farmers), which may represent surrogate markers of socioeconomic status. For example, although lack of access to latrines and infrequent shoe use are more likely to be seen in poorer communities, providing latrines or shoes does not impact the prevalence of soil-transmitted helminth infections.

School-age children with hookworm infection were nearly three times more likely (OR = 2.84; 95% CI = 1.11, 7.26) to have a positive malaria smear at baseline than those who were hookworm-negative (Table 2), and this age cohort also had the highest prevalence of coinfection (51%) (Figure 2B). Effects of concurrent helminth infection on the prevalence and clinical severity of malaria have been studied; however, the data are inconclusive, and mechanisms are poorly defined. For example, a cross-sectional study of school-age children in Tanzania found a higher prevalence of helminth infection (hookworm or Schistosoma mansoni) among children with *P. falciparum*, although a comparable study of younger children (6–23 months) found a lower prevalence. A deworming trial in Nigeria showed a significantly reduced rate of increase in malaria prevalence and intensity among children who were treated with albendazole. Two studies in Thailand found that *Ascaris* coinfection was associated with a decreased risk of cerebral malaria, although a prospective study by the same authors found a higher risk. A recent study by Pullan and others reported significant clustering (spatial and household) of hookworm and malaria infections in Uganda as well as evidence of an association between the two in pre–school-age children. Other studies have found no association between hookworm and malarial episodes, and the interpretation of existing data is complicated by differences in study populations, presence of multiple helminth species, variations in helminth infection intensities, and variations in the definition of infection status and risk of anemia in school-age children (6–15 years).

malaria. Given the complexity of the relationship between these two highly endemic parasitic diseases, it is difficult to draw conclusions about the degree to which one may have influenced susceptibility to the other in the Kintampo North study population.

Both hookworm infection and malaria are known to cause anemia, especially in children and women of childbearing age. In this study population, the risk of anemia among children ages 6–15 years was highest in those who had isolated malaria infection (OR = 4.92), and this risk was greater than in those who were infected with both hookworm and malaria (OR = 2.34) (Table 3). Despite the small sample size, this pattern (greater risk of anemia with isolated malaria infection compared with coinfection) was observed across three of four age groups studied, the exception being adults ages 16–40 years old (data not shown). Our findings are consistent with previous reports, including a study in Zanzibar that found children aged 6–11 years with lower height for age z score (HAZ) and weight for age z score (WAZ) scores had significantly higher risks of reinfection with *Ascaris* 8 months after completing treatment. Similarly, rural schoolchildren in Malaysia who were stunted had significantly higher rates of reinfection with STNs and a study in Brazil found a significantly higher rate of reinfection in undernourished children (38%) than in those who were well-nourished (25%). Ultimately, a greater understanding of the influence of nutritional status on susceptibility to helminth infections could inform future strategies aimed at integrating dietary supplementation with deworming programs.

We also observed an association in children between infection status and total IgG antibody levels against pooled adult hookworm ES proteins. It has previously been noted that infected individuals from endemic populations exhibit strong humoral response to various worm antigens and that certain immunoglobulin subtypes may be more closely associated with infection status. The serologic data presented here show that ES proteins from the human and animal hookworm *A. ceylanicum* can serve as useful reagents for measuring parasite-specific antibody responses in sub-Saharan Africa. This finding confirms significant cross-reactivity between ES proteins of *A. ceylanicum* and those from the two most common human hookworm species in Ghana, *A. duodenale* and *N. americanus*. Also, the observation that levels of IgG correlate with infection status, at least in children, validates the use of *A. ceylanicum* as a source of potentially relevant hookworm antigens that can be identified based on reactivity with human sera. Because the laboratory model of *A. ceylanicum* infection recapitulates the clinical features of human hookworm infection, specific ES antigens recognized by infected individuals may represent valuable targets for human drug and vaccine development.

It is interesting to note that, among the three most common STN infections (i.e., hookworm, ascariasis, and trichuriasis), only hookworm was present in significant numbers in the study population. The reason for this marked disparity in Kintampo North is not known, because central Ghana is known to be endemic for the three major STNs. Although we were unable to document evidence of prior albendazole exposure, this region of Kintampo North has participated in an intensive government sponsored onchocerciasis control program, which relies on periodic mass drug administration (MDA) with ivermectin. Ivermectin has modest efficacy against hookworm compared with other STNs, and MDA programs for onchocerciasis can alter the epidemiology of STN infections. For example, in the study by Moncaya and others, a reduction in *T. trichiura* prevalence because of ivermectin therapy was associated with a marked increase in the prevalence of hookworm.

Figure 5. Comparison of anthelmintic activity of two preparations of albendazole using *in vitro* egg hatch assay. No difference in activity was observed between the Remedica and Sigma albendazole preparations against a laboratory strain of hookworm (*A. ceylanicum*).
Although administration of albendazole was associated with an overall egg reduction rate of 81% in the study population, treatment failed to eliminate fecal egg excretion in more than one-third (39%) of subjects on follow-up exam. For comparison, the efficacy of albendazole ranges from 45% to 100% in published studies, placing the cure rate in this study (61%) to the lower end of what has been reported. Outcome did not correlate with age, sex, occupation, community of residence, or pre-treatment intensity of infection, because nearly all of the subjects had light infections (<2,000 epg). To investigate the quality of the medication, we compared the albendazole preparation used in the study (Remedia) with newly purchased drug (Sigma) using an in vitro egg hatch assay, which showed no difference in activity against a laboratory strain of hookworm (Figure 5). Compliance was also not an issue, because the administration of albendazole was directly observed by members of the study team.

In the absence of an alternative explanation, the prospect of benzimidazole resistance in Kintampo North must be considered, especially because, among those who were not cured, there was no statistically significant difference between pre- and post-treatment fecal egg counts ($P = 0.084$). Although resistance to benzimidazoles among veterinary nematodes is widespread, genetically mediated resistance of human hookworms to this class of anthelminthic has not been confirmed. However, increasing treatment failure rates with pyrantel pamoate and mebendazole have resulted in these drugs no longer being recommended for the treatment of human hookworm infection.$^{16,84,88}$ Moreover, reduced in vitro activity of mebendazole has been observed in human hookworm isolates from Pemba Island, an endemic area known for high rates of treatment failure,${}^{86}$ compelling evidence of emerging resistance. Preliminary analysis of a 2010 follow-up study in Kintampo North points to an albendazole treatment failure rate of greater than 50% (Humphries D and others, unpublished observation), confirming the data reported here and raising further doubts about the effectiveness of this agent for the treatment of hookworm in Ghana.

In summary, results from a cross-sectional pilot study show a high prevalence of hookworm and malaria coinfec-tion in Kintampo North Municipality of central Ghana. In addition to validating previously recognized risk factors, including nutritional status, we have also shown a novel association between hookworm infection and antibody levels to ES proteins from A. ceylanicum. We also observed that the risk of anemia was lower in children coinfected with malaria and hookworm than in those with malaria alone, suggesting that hookworm may modulate the pathogenesis of $P$. falciparum. Lastly, the high rate of albendazole treatment failure observed in this population raises concerns about benzimidazole resistance, a finding that warrants further investigation in Ghana and throughout sub-Saharan Africa.

Received January 1, 2011. Accepted for publication February 4, 2011.

Acknowledgments: This work was presented in part at the 2009 annual meeting of the American Society of Tropical Medicine and Hygiene. The study was conducted under the auspices of the Ghana–Yale Partnership for Infectious Diseases Research. E.M. was supported by a Wilbur Downs International Health Research Fellowship from Yale University. B.B.-P. was supported by the Yale College Beckman Scholars Program. The authors would like to thank the people of Kintampo North Municipality for their participation in this study, the staff and administration of the Noguchi Memorial Institute for Medical Research, the Kintampo Rural Health Training School, and the University of Ghana. We would also like to thank Jon Vermeire and Dylan Davey for careful reading of the manuscript.
