INTRODUCTION

The fight against malaria between 2000 and 2012 has resulted in global reductions of 42% in mortality and 25% in incidence of malaria.1 This achievement can be attributed to the introduction of artemisinin-based combination therapies and improvement in diagnosis, but also to the major scale-up of vector control interventions, such as the mass distribution of long-lasting insecticide-treated nets (LLINs) and indoor residual spraying (IRS). The World Health Organization (WHO) recommends that in areas where malaria transmission is targeted by vector control, every person at risk should be protected by either LLINs or IRS. This goal is still to be achieved, but in the last decade, the global distribution of LLINs has increased considerably. For example, in the sub-Saharan African region, from 2010 to 2013, an estimated 443 million LLINs have been delivered, reaching a coverage of up to 60%, a dramatic improvement from only 10% coverage in 2000.1

A major threat for malaria control programs worldwide is the development and spread of insecticide resistance in vector populations. Unfortunately, the use of insecticides for both public health and agriculture has induced selective pressure(s) on numerous insect populations, including Anopheles mosquitos involved in malaria parasite transmission, resulting in the selection of highly resistant vector populations. According to the WHO, insecticide resistance is defined as the ability of an insect to withstand the effects of an insecticide by becoming resistant to its toxic effects by means of natural selection and mutations.2 Many malaria vector species have acquired multiple insecticide resistance as they have been exposed to a battery of insecticides since the eradication era of the 1950s. The reliance on insecticides to reduce vectorial capacity for malaria transmission control is thus facing a grave threat and becoming a major public health concern. The common mechanisms by which vectors acquire insecticide resistance are metabolic resistance (e.g., glutathione S-transferases, esterases, monooxygenases), target site resistance (e.g., mutations in acetylcholinesterase gamma-aminobutyric acid receptors, insensitivity of the sodium channels—kdr, or knock down resistance), reduced penetration, and behavioral avoidance.3

The goal of this communication is to review the current situation regarding insecticide resistance in the regions under study by nine out of the 10 National Institutes of Health (NIH) International Centers for Excellence for Malaria Research (ICEMRs). The ICEMRs have activity on all continents with malaria transmission; Africa has four ICEMRs: west Africa (Mali, Senegal, and The Gambia), Uganda (Uganda), southern Africa (Zambia and Zimbabwe), and Mali (Mali), from which the former three contributed to this manuscript. Latin America (LA) has two ICEMRs: LA (Guatemala, Panama, Colombia, and Perú) and Amazonia...
Resistance to pyrethroids (PY), the main insecticide group currently used for malaria control, is now widespread in African vectors. At the ICMR study sites in Zambia, An. gambiae s.s. is still completely susceptible to OP (malathion and fenitrothion) and the organochlorines (OC) (dichlorodiphenyltrichloroethane [DDT] and dieldrin) (Figure 1). However, strong resistance to DDT has been illustrated elsewhere in the country, and high levels of PY are widespread.

Anopheles funestus s.s. has shown similar resistance profiles in Zambia and Zimbabwe, being completely susceptible to DDT, dieldrin, and OPs (malathion, fenitrothion, and pirimiphos-methyl), but showing resistance to PYs (deltamethrin and lambda-cyhalothrin) and the carbamates (C) (bendiocarb and propoxur) (Figure 1).

The third major African malaria vector, Anopheles arabiensis, currently present at only one of the ICMR sites in southern Zambia, has been reported as fully susceptible to all classes of insecticides at this site.

In west Africa, the two major malaria vectors An. gambiae s.s. and An. funestus s.s. have previously been found to be potentially resistant to PY and DDT. In Senegal, an increase in the frequency of the kdr mutation in An. gambiae s.s. was observed when examined before and after the introduction of LLINs. Since then, that population of An. gambiae s.s. has shown resistance to DDT and PY insecticides (deltamethrin, lambda-cyhalothrin, and permethrin), with mortality rates ranging from 46% to 63%, but it remains completely susceptible to fenitrothion (OP) and bendiocarb (C). The use of pyrethroids as pesticides in agriculture and for bed net treatment has been recognized as a factor responsible for the selection of resistant mosquitoes in sub-Saharan Africa.

Tests carried out in Mali (Segou and Koulikoro regions) and Senegal (Thies region) showed high resistance levels to DDT in both An. gambiae s.s. and An. arabiensis, but susceptibility to bendiocarb (C) and pirimiphos-methyl (OP) (Figure 1). Any carbamate or OP could be introduced for IRS to replace pyrethroids for IRS as part of an insecticide resistance management (IRM) strategy in this region.

In the Uganda ICMR, An. gambiae s.s. and An. arabiensis have been found to occur in sympatry at all the three sites, namely Jinja, Tororo, and Kanungu, with the highest levels of An. arabiensis species composition (approximately 80% of all mosquitoes collected) found in Jinja. High levels of DDT, deltamethrin, and permethrin resistance have been observed in An. gambiae s.s. in Jinja, Tororo, and Kanungu (Figure 1). In contrast, no resistance to DDT has been observed in An. arabiensis from Jinja or Tororo (there is a very low abundance of An. arabiensis in Kanungu). However, resistance to deltamethrin and permethrin has been observed in An. arabiensis from both Jinja and Tororo.

In the LA region, Anopheles darlingi, the main malaria vector in LA, and particularly responsible for malaria transmission in the Amazon region, is generally susceptible to all insecticides throughout its distribution. However, a population in western Colombia (Choco) exhibited DDT resistance in the 1990s and to DDT and PY when resampled in 2005–2009.
Despite this resistance to DDT and PY, this population showed susceptibility to OP (malathion and fenitrothion). Apart from this particular population, in the Amazon region of Perú-Brazil (Amazonian ICEMR), along the Pacific coast (LA ICEMR) and in other areas in LA, this species shows complete insecticide susceptibility (Figure 2).

Anopheles albimanus has also been subjected to insecticide resistance surveillance throughout its range in the Americas. In Central America, resistance to a variety of insecticides was reported in 1970 and associated mainly with insecticide use in agriculture. In Panama, this species has demonstrated resistance to PYs (cyfluthrin, cypermethrin, deltamethrin, and lambda-cyhalothrin), and susceptibility to OPs (malathion and fenitrothion) (Figure 2). In contrast, this species has shown an alarming resistance to all insecticides evaluated in northwestern coastal Peru. As shown in Figure 2, lower than 95% mortality rates have been recorded for the bendiocarb (C), OCs such as DDT, OPs (malathion and fenitrothion), and all PYs evaluated (permethrin, cyfluthrin, cypermethrin, deltamethrin, and lambda-cyhalothrin).

The distribution pattern of An. albimanus in Peru overlaps with rice cultivation areas where insecticides are used frequently, and it is likely that this pressure has influenced the selection of resistance in vector populations.

Anopheles nuneztovari s.l. is one of the main vectors of malaria in Colombia and Venezuela. This species has been described as endophagic but exophilic, with a tendency to avoid contact with walls sprayed with insecticides. In a series of evaluations conducted in Colombia, this species exhibited insecticide resistance in a population on the border between Colombia and Venezuela to PYs, OPs, and DDT (Figure 2). Similarly, Anopheles benarrochi and Anopheles pseudopunctipennis are considered of importance as vectors in Peru.

Anopheles benarrochi is susceptible to PY, except for a population from Ucayali (on the border with Brazil) that demonstrated resistance to permethrin, whereas An. pseudopunctipennis from Cajamarca, in the northwest of the country has shown less than 95% mortality for all insecticides tested (permethrin, deltamethrin, lambda-cyhalothrin, cypermethrin, and malathion) (Figure 2).

In general, resistance in vectors in LA is focal, probably due to insecticide pressure from agriculture use. Most importantly, at this time, the primary vector in LA, An. darlingi, has shown susceptibility through most of its distribution, except for one population in Colombia.

Given the local availability of supplies for the CDC bioassay, this methodology is performed in Colombia every year at sentinel sites selected by the insecticide resistance surveillance network (IRSN). In Peru, this surveillance is based on the WHO bioassay, but in some localities the CDC bottle bioassay has also been used by the malaria control program and Amazonian ICEMR. CDC results compatible with suspected resistance are confirmed by WHO methodology whenever possible. Although both methods report percentage mortalities, the results from the CDC bottle bioassay are not directly comparable with those obtained from the WHO susceptibility tube test even though both methods have been shown to reliably identify insecticide resistance where it occurs.

To directly compare these methods, WHO and CDC tests were conducted simultaneously on the same mosquito
populations from 64 localities in Colombia and Peru. Following the new WHO criteria of mortalities, below 98% being suggestive of the existence of resistance, these two tests gave identical results in 84.4% (54/64) of the comparisons, identifying 45 susceptible and 9 resistant populations.

**Figure 2.** Latin American (LA) region, including countries in the LA and Amazonia International Centers of Excellence for Malaria Research: summary of insecticide susceptibility status of malaria vectors showing the proportion of mosquitoes killed in susceptibility bioassay tests, by country and site.
remaining 15.6% (10/64) of comparisons did not match; in six populations, the mortality rate by the WHO method was between 81% and 97%, whereas for the CDC bottle bioassay it was 100%; and in four populations, 100% mortality was obtained using the WHO test, but the CDC bottle bioassay mortalities ranged between 48% and 83%. The Kappa index for the 64 locality comparisons was 0.544, interpreted as moderate agreement between the methods.29 Whenever there are discrepancies between methods, IRSN recommends synergists be used together with biochemical methods for confirmation and determination of the possible resistance mechanisms in that particular population.28 Despite the discrepancies noted above, either method can be used in a routine surveillance system for early detection of resistance and to support decisions on the appropriate management of vector populations.

Pacific region. Anopheles farauti s.l. populations composed of An. farauti, Anopheles punctulatus, and Anopheles hinesorum from five study sites in the Madang, Manus, and east Sepik provinces in Papua New Guinea were tested for susceptibility to the PYs deltamethrin and lambda-cyhalothrin and the presence of the kdr allele.30 All populations (An. farauti s.s. in Manus and two sites in Madang, An. punctulatus in east Sepik and anophelines composed of both An. hinesorum and An. punctulatus) were 100% susceptible (Figure 3) with no detection of the kdr allele. Further screening for the kdr genotype in wild-caught adult An. punctulatus s.l. (N = 90) collected from seven different PNG provinces did not detect kdr allele in any of the An. punctulatus species.31

Similar results with the WHO paper test were found in 2014 in the Solomon Islands where 100% susceptibility to deltamethrin was shown in An. farauti s.s. from the western Province (Cooper, unpublished), Temotu, Central, Choiseul, and Malaita (Bugoro, unpublished). However, in 2013, moderate resistance to lambda-cyhalothrin was found in Malaita and Central provinces, to permethrin in Central and Guadalcanal provinces, and to deltamethrin in Guadalcanal (Bugoro, unpublished).

The absence of high levels of resistance recorded in many geographic areas is not surprising given the well-documented development of behavioral resistance in An. farauti s.l. following exposure to DDT used in IRS in both Papua New Guinea and the Solomon Islands.32,33 The behavioral resistance phenotype observed is a shift toward earlier feeding with a higher proportion of feeds occurring outdoors. Such feeding shifts prevent insecticide exposure of the vector to IRS-treated walls and/or pyrethroids in insecticide-treated nets.34

South Asia (India). India has six primary vectors of malaria; Anopheles culicifacies, Anopheles stephensi, Anopheles fluviatilis, Anopheles minimus, Anopheles dirus (Anopheles baimai), and Anopheles sundacius. The first three species have been subjects for determination of insecticide susceptibility and are responsible for most of the malaria transmission in the region. There are two ICEMRs in India. The first is Malaria Evolution in South Asia with operational sites in Goa, Wardha (Maharashtra), Ranchi (Jharkhand), and Dibrugarh (Assam) where An. stephensi, An. culicifacies, An. minimus, and An. dirus (An. baimai) are the main vectors. The second ICEMR is Center for the Studies of Complex Malaria in India with an urban site, Chennai, with the urban malaria vector An. stephensi, and two rural sites in Gujarat and Odisha states where An. culicifacies and An. fluviatilis are the main vectors. Anopheles culicifacies is resistant to DDT and malathion in most districts of Odisha and in other states, and highly resistant to deltamethrin although a few regions retain sensitive populations.35,36 In general, the problem of DDT resistance in An. culicifacies is acute in Odisha, Madhya Pradesh, and Chhattisgarh (Figure 4). In Odisha, a highly malarious state of India, the resistance to deltamethrin in An. culicifacies is increasing, whereas other populations remain fully susceptible.30 In Chhattisgarh state, resistance to deltamethrin in An. culicifacies is also increasing. In Tamil Nadu, the susceptibility status of An. culicifacies from Rameswaran Island to deltamethrin (0.05%) and cyfluthrin (0.15%) was compared with the strains from Subbareddipalayam, an adjoining area located in the northern outskirts of Chennai city. Another study in Rameswaran Island in Tamil Nadu, has also reported reduced susceptibility to deltamethrin in An. culicifacies.37 In a study in Surat, Gujarat, development of pyrethroid resistance has been reported in sibling species, B and C of An. culicifacies.38 In contrast, the sibling species An. fluviatilis S is also a dominant vector in Odisha. So far, An. fluviatilis remains completely susceptible to all insecticides including pyrethroids and DDT used for vector control and OPs used for agricultural purposes.36

The principal urban vector in India, An. stephensi, has been reported to be resistant to malathion in Goa,39 whereas low-level resistance as well as complete susceptibility have been observed in two native populations in Rajasthan. Anopheles stephensi was highly susceptible to deltamethrin in Rajasthan and Gujarat, and lambda-cyhalothrin in Karnata state.40 In Goa, resistance to deltamethrin is building, whereas this species was highly resistant to DDT in Rajasthan, Gujarat, and Goa.41 In one location in Karnataka state, however, a population of An. stephensi was found to be highly susceptible.
FIGURE 4. South Asian region, including India and south Asia International Centers of Excellence for Malaria Research: summary of insecticide susceptibility status of malaria vectors showing the proportion of mosquitoes killed in susceptibility bioassay tests, by country and site.

FIGURE 4. Continued.
to DDT, illustrating the heterogeneity in these resistance patterns (Figure 4). Bioassays with cyfluthrin showed that > 95% mortality occurred in this species in Karnataka, whereas in Goa, complete susceptibility was earlier observed to pirimiphos-methyl.43

In An. subpictus, the vectorial capacity of which is under investigation, widespread DDT (OC) and malathion (OP) resistance was reported from Rajasthan and Gujarat (Figure 4). Many populations of this species tested in Gujarat and Rajasthan also showed some degree of resistance to deltamethrin (PY). In contrast, in Odisha, complete susceptibility to DDT, malathion, and deltamethrin has been found in An. fluvialis, an important malaria vector in the hills and foothills in India45 (Figure 4).

**SE Asia.** In SE Asia, malaria vectors are highly diverse in species composition, population dynamics, ecological niche requirement, host feeding preference, and vector competence.46 Malaria vector species in SE Asia exhibit tremendous spatial heterogeneity in distribution. For example, in tropical and sub-tropical regions of China (below 25°N latitude), An. minimus s.l. and An. dirus s.l. are the main vectors, whereas in more temperate regions (above 33°N latitude), Anopheles sinensis is the major malaria vector.46

In the areas between 25°N latitude and 33°N latitude, Anopheles anthropophagus and Anopheles liangshenensis are important regional malaria vectors. In Thailand, in addition to An. dirus and An. minimus, Anopheles maculatus and Anopheles aconitus are considered to be primary human malaria vectors.46

Reducing vector-human contact by the use of LLINs has been shown to be effective in reducing malaria prevalence in SE Asia.47 Along with the use of insecticides to reduce abundance of disease vectors, the application of insecticides for agricultural purposes increases the likelihood and speed at which resistance can develop.48

Previous studies in SE Asia suggest a patchy distribution of insecticide resistance in four malaria vector species. Between 1990 and 1997, DDT resistance has been detected in An. dirus s.l. and An. minimus s.l., and permethrin resistance was also found in a population of An. minimus s.l. from northern Thailand.46 In Vietnam, pyrethroid-susceptible and pyrethroid-tolerant An. minimus populations were found, and An. minimus also showed resistance to DDT (OC) and pyrethroids in some sites in Cambodia and Laos.49 Anopheles dirus s.s., the main vector in forested malaria foci, was permethrin susceptible throughout the Mekong region, but in central Vietnam it showed possible resistance to pyrethroids.49 In 2006, resistance to deltamethrin was reported in An. sinensis in China.50 Recently, extensive and high level of multiple insecticide resistance was found in An. sinensis (Figure 5) from the malaria-endemic areas in China.51,52 The patchy distribution of resistant genes in the vector population will require resistance monitoring to limit the spread of resistance genes among populations.

**DISCUSSION**

With few exceptions, such as the Pacific and Amazon regions, most countries involved with the NIH ICEMR research programs are facing significant problems with insecticide resistance. Of tremendous concern are the growing resistance levels to pyrethroids illustrated in many regions and for the most important malaria vector species. This class of insecticides is currently the only suitable ones for LLINs, and in many regions, pyrethroids are also used for IRS. In most African countries, DDT and PY resistance mediated in part by metabolic resistance and/or kdr is widespread,53 and occurs even in a relatively short period of time after the introduction of mass distribution campaigns of LLINs, as has been the case in Senegal.54 The use of OP or carbamates for IRS seems to be the alternative, which has an economic impact on the malaria control programs not only for the higher cost of these classes of insecticides compared with PY but also for the operational cost due to the need of applications two or three times a year, depending on the transmission seasons.

Some regions, such as the Indian and SE Asian subcontinents, have a diverse range of vector species responsible for malaria transmission of Plasmodium falciparum, Plasmodium vivax, and Plasmodium malariae, with enormously varied resistance patterns. Anopheles culicifacies is responsible for approximately 65% of the total malaria cases in India and resistance in this species to almost all classes of insecticide threatens malaria control.54 In addition, two of the principal vectors of malaria in India, An. culicifacies and An. stephensi, are resistant to multiple insecticides although resistance varies dramatically between populations, apparently depending on the history of insecticide use and selection. Some important vectors (e.g., An. fluvialis), however, show remarkable susceptibility to most insecticides, as depicted here (Figure 4), and there is need to investigate the resistance status of other vectors in India, that is, An. sundacius, An. dirus, and An. minimus. In SE Asia, the situation is more problematic for the main vector An. sinensis, since resistance to all classes of insecticides is at high levels and long-term rotational use of various insecticides has led to the selection of this high insecticide resistance.55 This is a clear call for urgent development and expansion of non-insecticide-dependent tools for vector management, such as larvivorous fish and source reduction, as used as part of India’s Urban Malaria Scheme.55
Strategies for Integrated Vector Management (IVM) emphasize the need for the development of new insecticides, and the evaluation and implementation of alternative approaches because current options are limited. Where malaria vector populations are still susceptible to pyrethroids, that is, LA and the Pacific, it is essential to preserve future use through regular assessment of susceptibility status and, most importantly, the implementation of an appropriate IRM plan to minimize the risks of developing resistance.

Few contemporary successful initiatives using alternative approaches as complementary control measures have been documented. Intensive environmental interventions to reduce Anopheles populations in semiarid environments in Eritrea and the initiatives in Mexico and Central America to stop the use of DDT, in which physical destruction of larval habitats or removal of filamentous algae associated with abundance of Anopheles larvae (i.e., An. pseudopunctipennis), led to an important reduction in the mosquito vector populations. In most countries, however, strategies against larval habitats are unlikely to be addressed due to the difficulty in identifying the breeding sites, site diversity, opportunistic use for most vector species of many water sources, and expense associated with and scale necessary for landscape modification. Furthermore, control methods against adult mosquito populations, particularly those which reduce their survival rate, may have a greater direct impact on malaria transmission. Unfortunately, few alternatives to existing insecticides are currently available and recommended for global incorporation in malaria control programs.

Resistance management strategies include rotation of insecticides with different modes of action and resistance mechanisms, or mosaic applications. However, it is becoming more common to find populations that have been exposed to different groups of insecticides from use in public health and/or agriculture, and the emergence of multiple resistance, or populations in which a resistance mechanism is causing cross-resistance to multiple compounds, especially if those compounds are in different classes of insecticides. Usually, when results of the susceptibility bioassays indicate emerging or emergent resistance, malaria control program authorities make decisions regarding the necessary change of insecticides in that particular area. However, these bioassays do not provide any information on the strength of this resistance, and, because the correlation between results of diagnostic dose assays and control effectiveness remains undefined, simple detection of resistance in a mosquito population is often not sufficient evidence to implement a change in insecticide policy. Recently, an intensity test has been proposed to quantify the strength of resistance, which will give more information on the level of resistance that may lead to operational failure. Besides physiological and genetic insecticide resistance, another challenge is behavioral resistance where vectors feed and rest outdoors as is seen with the main malaria vectors in LA and other regions. This behavior can be induced by extensive indoor vector control whereby previously endophilic species become more exophilic and avoid treated surfaces such as walls or bed nets. This is the case of An. farauti in Papua New Guinea where despite full physiological susceptibility to PY, a change in behavior to avoid surfaces with insecticides is creating an enormous challenge for malaria control. In Africa, outdoor transmission is a growing concern since major changes are taking place in which parasite transmission is shifting from the dominant and highly endophilic vector, An. gambiae s.s., to the more exophilic and outdoor-adapted vector, An. arabiensis. Also, new findings report entirely exophilic An. gambiae s.s. populations with high susceptibility to P. falciparum. Tools to effectively manage this outdoor and early evening transmission are urgently needed and although this behavioral trend may reduce insecticide resistance, it is a challenge for malaria control, particularly in countries moving toward malaria elimination.

As evident in the 10 ICEMR programs distributed throughout the malarious regions of the world, insecticide resistance is a growing and alarming problem for malaria control programs. Novel insecticides and alternative strategies are desperately needed for vector control, and would be better coupled with IVM and IRM programs. The hope is that future malaria control programs will have the tools to better integrate vector control with complementary antimalarials or vaccines that reduce or prevent parasite loads in hosts. Realistically, in the next 15 or more years, vector control will remain an essential component of malaria control programs.
